Abstract: A mathematical model of Zika virus transmission, incorporating human movement between rural areas and nearby forests, is presented to investigate the role of human movement in the spread of Zika virus infections in human and mosquito populations. Proportions of both susceptible and infected humans living in rural areas are assumed to move to nearby forest areas. Direct, indirect, and vertical transmission routes are incorporated for all populations. A mathematical analysis of the proposed model is presented. The analysis starts with normalizing the proposed model. The positivity and boundedness of solutions to the normalized model are then addressed. The basic reproduction number is calculated using the next-generation matrix method and its relation to the three routes of disease transmission has been presented. The sensitivity analysis of the basic reproduction number to all model parameters is investigated. The analysis also includes the existence and stability of disease-free and endemic equilibrium points. Bifurcation analysis is also carried out. Finally, numerical solutions to the normalized model are obtained to confirm the theoretical results and demonstrate human movement’s role in disease transmission in human and mosquito populations.

I. INTRODUCTION

Zika is an arboviral disease in the genus flavivirus closely related to yellow fever, West Nile (WN), and dengue (DEN) viruses. It was first identified in 1947 in Zika Forest in Uganda during sylvatic yellow fever surveillance in a sentinel rhesus monkey [1]. In 1954, it was reported in humans for the first time in Nigeria [2]. The Zika epidemic was stated as a Public Health Emergency of International Concern (PHEIC) by the World Health Organization (WHO) on February 1st, 2016 [3]. It has attracted global attention since its worldwide spread among tropical and subtropical regions. In Yap Island, Micronesia in 2007, the first Zika outbreak occurred among humans [4]. During 2013-2014 the largest epidemic of Zika ever reported was in French Polynesia [4]. Since 2014, the Zika virus (ZIKV) has continued spreading to other pacific islands [2]. It reached southern and Central America after 2015 and Brazil and the Caribbean were highly affected by ZIKV [4]. Local transmission of ZIKV was realized in 34 countries by March 2016 [5].

ZIKV is transmitted primarily to the human popu-
Zika disease is characterized by mild symptoms including fever, headache, maculopapular rash, joint and muscle pain, conjunctivitis, etc. The clinical symptoms duration is within two to seven days after the bites [3]. Most reports show that Zika is a self-limiting febrile disease that could be misidentified as dengue or chikungunya fever [7].

The prevention of mosquito bites and control of vectors by using insecticide, eradication of adult and larval breeding areas is the only possible treatment available till now [8].

Understanding virus transmission and disease epidemiology through mathematical modelling are of great importance for disease management. Several mathematical models have been developed to study the dynamics and propose control strategies for the transmission of ZIKV disease. In [3], the authors proposed a Zika mathematical model by assuming the standard incidence type interaction of human-to-human transmission of the illness. Also, they extended their work to include optimal control programs (insecticide-treated bed nets, mosquito-repulsive lotions, and electronic devices) to reduce the biting rate of vectors, and to decline the spread of the disease among the human population. In [8], authors proposed a Zika mathematical model including the applications of prevention, treatments, and insecticide as the best way to minimize the spread of ZIKV disease. In [9], researchers suggested a multi-fold Zika mathematical model. They considered the transmission of the ZIKV in the adult population and infants either directly by vector bites or through vertical transmission from mothers. The model shows that asymptomatic individuals magnify the disease weight in the community. It also indicated that postponing conception, coupled with aggressive vector control and personal protection use, decrease the cases of microcephaly and transmission of ZIKV.

Globally, the survival of around 1.6 billion rustic people depends on products obtained from local forests, in whole or in part. Those individuals live adjacent to the forest and have had simple survival conditions and livelihoods for many generations. They depend on those natural and wild resources to meet their needs [10].

In this paper, a mathematical model of ZIKV is constructed to demonstrate the specific and realistic conditions, where the nearby movement of humans may contribute to the spread of virus infections. This happens when an infected human with mild symptoms, moves from rural areas to nearby forest areas looking for work or food. Additionally, the movement of a susceptible human can affect the spread of infections via contagious mosquitoes in the forest. Hence, in this paper, we have split the vector compartment, based on mosquito location, into rural areas and nearby forest areas. Human movement between rural areas and their interaction with vector populations are illustrated in Figure 1. In addition, sexual and vertical transmissions in the human population are considered. Also, vertical transmission from a contaminated female mosquito to its offspring, is suggested as a component that guarantees the upkeep of ZIKV.

The paper is organized as follows. The model formulation is described in Section 2. The model analysis includes the positivity, boundedness of the solution, basic reproduction number, and sensitivity analysis are discussed in Section 3. Furthermore, stability analysis and bifurcation analysis are presented. A numerical analysis of the model using assumed baseline parameters is given in Section 4 to illustrate the effects of highly sensitive parameters on the human population. Finally, the conclusion is given in Section 5.

II. MODEL DESCRIPTION

In this section, we introduce a model for ZIKV transmission between humans and vectors in rural areas and nearby forests. We begin the description of the model with the human compartments. We split the human population into susceptible $S_h$, symptomatic $I_h$ and recovered $R_h$. Susceptible humans $S_h$ can get infected with Zika via three main routes [11]: via a mosquito bite (vector transmission), via sexual transmission or blood transfusion (direct transmission), or by being passed from a mother to a newborn child (vertical transmission).

Zika causes nearly no mortality among humans and has been a public health crisis for a relatively short pe-
I may get infected by infectious mosquitoes that live in rural areas to forest areas, and a proportion \( \varepsilon_3 \) of newborns are affected and enter the symptomatic class. Evidence suggests that the fraction is about 2/3 [12].

The set of non-linear differential equations that represents the proposed mathematical model is given by:

\[
S_h' = \mu_H N_H - \mu_H \varepsilon_1 I_h - (1 - \kappa_1) \beta_1 \theta_1 I_v \frac{S_h}{N_H} - \kappa_1 \beta_2 \theta_1 I_u \frac{S_h}{N_H} - \mu_H S_h - \kappa_1 \beta_2 \theta_1 I_u \frac{S_h}{N_H} - \mu_H S_h + \kappa_2 \theta_1 \beta_2 S_u \frac{I_h}{N_H} - (\gamma + \mu_H) I_h \\
I_h' = \mu_H \varepsilon_1 I_h - (1 - \kappa_1) \beta_1 \theta_1 I_v \frac{S_h}{N_H} + \kappa_1 \beta_2 \theta_1 I_u \frac{S_h}{N_H} + \kappa_2 \theta_1 \beta_2 S_u \frac{I_h}{N_H} - \mu_U I_u + (1 - \kappa_1)(1 - \kappa_2)\lambda I_h \frac{S_h}{N_H} - (\gamma + \mu_H) I_h \\
R_h' = \gamma I_h - \mu_H R_h \\
S_v' = \mu_V N_V - \mu_V \varepsilon_2 I_v - (1 - \kappa_2) \beta_2 \theta_2 S_v \frac{I_h}{N_H} - \mu_V S_v \\
I_v' = \mu_V \varepsilon_2 I_v + (1 - \kappa_2) \beta_2 \theta_2 S_v \frac{I_h}{N_H} - \mu_V I_v \\
S_u' = \mu_U N_U - \mu_U \varepsilon_3 I_u - \beta_2 \theta_2 \kappa_2 S_u \frac{I_h}{N_H} - \mu_U S_u \\
I_u' = \mu_U \varepsilon_3 I_u + \beta_2 \theta_2 \kappa_2 S_u \frac{I_h}{N_H} - \mu_U I_u
\]

with non-negative initial conditions \( S_h(0), I_h(0), R_h(0), S_v(0), I_v(0), S_u(0), I_u(0) \). In addition, the parameters and their values of the system are defined in Table 1.

Let

\[
S_H = \frac{S_h}{N_H}, \quad I_H = \frac{I_h}{N_H}, \quad R_H = \frac{R_h}{N_H}, \\
S_V = \frac{S_v}{N_V}, \quad I_V = \frac{I_v}{N_V}, \quad S_U = \frac{S_u}{N_U}, \quad I_U = \frac{I_u}{N_U},
\]

such that

\[
S_H + I_H + R_H = 1, \quad S_V + I_V = 1, \quad S_U + I_U = 1.
\]

Thus, the considered model (1) have been normalized and rewritten as follows:

\[
S_h' = \mu_H - \mu_H \varepsilon_1 I_h - \pi_1 \beta_1 \theta_1 \alpha_1 I_v S_H \\
- \kappa_1 \beta_2 \theta_1 \alpha_2 I_u S_H - \kappa_1 \beta_2 \theta_2 \lambda I_h S_H - \mu_H S_H \\
I_h' = \mu_H \varepsilon_1 I_h + \pi_1 \beta_1 \theta_1 \alpha_1 I_v S_H + \kappa_1 \beta_2 \theta_1 \alpha_2 I_U S_H \\
+ \kappa_2 \beta_2 \theta_2 \lambda I_h S_H - (\gamma + \mu_H) I_h \\
R_h' = \gamma I_h - \mu_H R_h \\
S_v' = \mu_V - \mu_V \varepsilon_2 I_v - \pi_2 \beta_2 \theta_2 S_v I_H - \mu_V S_V \\
I_v' = \mu_V \varepsilon_2 I_v + \pi_2 \beta_2 \theta_2 S_v I_H - \mu_V I_v \\
S_u' = \mu_U - \mu_U \varepsilon_3 I_u - \beta_2 \theta_2 \kappa_2 S_u I_H - \mu_U S_u \\
I_u' = \mu_U \varepsilon_3 I_u + \beta_2 \theta_2 \kappa_2 S_u I_H - \mu_U I_u

III. MODEL ANALYSIS

In this section, the positivity of solutions, the positive invariant set, and the basic reproduction number are discussed. Also, sensitivity analysis and results related to stability analysis and bifurcation analysis are presented.

A. Positivity of Solutions and Positively Invariant Set

It is clear that model (1) together with the given non-negative initial condition has a unique solution. Next, we show that all solutions remain non-negative for all \( t \in [0, \infty) \) for arbitrary choice of initial con-
ditions to have an epidemiological convincing result. The following theorem demonstrates the positivity and boundedness of state variables:

**Theorem 1.** The solutions $S_H(t)$, $I_H(t)$, $R_H(t)$, $S_V(t)$, $I_V(t)$, $S_U(t)$ and $I_U(t)$ of system (2) with non-negative initial conditions $S_H(0)$, $I_H(0)$, $R_H(0)$, $S_V(0)$, $I_V(0)$, $S_U(0)$, $I_U(0)$ remain non-negative for all time $t \geq 0$ in a positively invariant closed set

$$\Omega := \left\{ (S_H, I_H, R_H, S_V, I_V, S_U, I_U)^T \in \mathbb{R}_+^7 : 0 \leq S_H(t), I_H(t), R_H(t), S_V(t), I_V(t), S_U(t), I_U(t) \leq 1 \right\}.

**Proof:** Assume that the initial conditions of the system (2) are non-negative. Let $t_1 > 0$ be the first time at which there exists at least one component which is equal to zero and other non-negative components are non-negative on $[0, t_1)$. In the following, we will show that none of the components can be zero at $t_1$. Let’s first assume that $S_H(t_1) = 0$ and other components are non-negative on $[0, t_1)$. Now, $S_H'$ can be written as

$$S_H' = \mu_H (1 - \varepsilon_1) + \mu_H \varepsilon_1 R_H - m_1 S_H - \mu_H (1 - \varepsilon_1) S_H,$$

where

$$m_1 = \kappa_1 \beta_1 \alpha_1 I_V + \kappa_1 \beta_2 \alpha_2 I_U + \kappa_1 \kappa_2 \lambda I_H > 0.$$

Then, at $t_1$, we have

$$\frac{S_H(t)}{dt} \bigg|_{t=t_1} = \mu_H (1 - \varepsilon_1) + \mu_H \varepsilon_1 R_H(t_1) > 0,$$

which means that $S_H(t)$ is strictly monotonically increasing at $t_1$, that is $S_H(t) < S_H(t_1)$ for all $t \in (t_1 - \varepsilon, t_1)$, where $\varepsilon > 0$. Since $S_H(t_1) = 0$, then, $S_H(t) < 0$ on $(t_1 - \varepsilon, t_1)$. This leads to a contradiction. Therefore, $S_H(t)$ cannot be zero at $t_1$.

Now, we assume that $I_H(t_1) = 0$ and other components are non-negative. Then

$$\frac{I_H(t)}{dt} \bigg|_{t=t_1} = S_H(t_1) (\bar{\kappa}_1 \beta_1 \alpha_1 I_V(t_1) + \kappa_1 \beta_2 \alpha_2 I_U(t_1)) > 0,$$

which means that $I_H(t)$ is strictly monotonically increasing at $t_1$. Hence, we also get a contradiction.

Next, assume that $R_H(t_1) = 0$ and other components are non-negative. Then

$$\frac{R_H(t)}{dt} \bigg|_{t=t_1} = \gamma I_H(t_1) > 0,$$

which again leads to a contradiction.

Similarly, one can prove that the remaining components of vector populations $S_V(t)$, $I_V(t)$, $S_U(t)$, $I_U(t)$ cannot be zero at $t_1$. Hence, from the above, we conclude that such a point $t_1$ at which at least one component is zero does not exist. Hence, all components remain non-negative for all time $t \geq 0$.

For the positively invariant closed set $\Omega$, we first note that the set $\Omega$ is said to be positively invariant if the initial conditions are in $\Omega$ implies that

$$\left( S_H(t), I_H(t), R_H(t), S_V(t), I_V(t), S_U(t), I_U(t) \right)^T \in \Omega.$$

Let

$$\Phi(t) = (\Phi_1(t), \Phi_2(t), \Phi_3(t))^T,$$

where

$$\Phi_1(t) = S_H(t) + I_H(t) + R_H(t),$$

$$\Phi_2(t) = S_V(t) + I_V(t),$$

$$\Phi_3(t) = S_U(t) + I_U(t).$$

Then

$$\Phi'(t) = \begin{bmatrix} \mu_H - \mu_H \Phi_1(t) \\ \mu_V - \mu_V \Phi_2(t) \\ \mu_U - \mu_U \Phi_3(t) \end{bmatrix}.$$

Now, solving for $\Phi_1$, $\Phi_2$ and $\Phi_3$, we get

$$\Phi_1(t) = 1 - (1 - \Phi_1(0)) e^{-\mu_H t},$$

$$\Phi_2(t) = 1 - (1 - \Phi_2(0)) e^{-\mu_V t},$$

$$\Phi_3(t) = 1 - (1 - \Phi_3(0)) e^{-\mu_U t},$$

where

$$\Phi_1(0) = S_H(0) + I_H(0) + R_H(0),$$

$$\Phi_2(0) = S_V(0) + I_V(0),$$

$$\Phi_3(0) = S_U(0) + I_U(0).$$

It is straightforward to conclude that

$$\Phi_1(t) \leq 1 \quad \text{if} \quad \Phi_1(0) \leq 1,$$

$$\Phi_2(t) \leq 1 \quad \text{if} \quad \Phi_2(0) \leq 1,$$

$$\Phi_3(t) \leq 1 \quad \text{if} \quad \Phi_3(0) \leq 1.$$

Thus, we have

$$0 \leq S_H(t), I_H(t), R_H(t), S_V(t), I_V(t),$$

$$S_U(t), I_U(t) \leq 1$$

and hence the set $\Omega$ is positively invariant set. Moreover, the set $\Omega$ is a globally attractive set since if $\Phi_i(0) > 1$ then $\lim_{t \to \infty} \Phi_i(t) = 1$ for $i = 1, 2, 3$. ■
B. The Basic Reproduction Number

The model (2) has a disease-free equilibrium (DFE): 
\[ Z^0 := (S^0_H, 0, 0, S^0_V, 0, S^0_U, 0) \in \Omega, \]
where \( S^0_H = S^0_V = S^0_U = 1. \)

The number of new infections produced by a typical infected individual in a population at DFE is called the basic reproduction number \( R_0 \) which can be obtained by applying the Next Generation Method [20]. The next-generation matrix is:
\[
PQ^{-1} = \begin{bmatrix}
\lambda \kappa_1 \kappa_2 & \pi_1 \alpha_1 \beta_1 \theta_1 & \kappa_1 \alpha_2 \beta_2 \theta_2 \\
\gamma + \mu_H (1 - \varepsilon_1) & \mu V (1 - \varepsilon_2) & \mu U (1 - \varepsilon_3) \\
\gamma + \mu_H (1 - \varepsilon_1) & 0 & 0 \\
\gamma + \mu_H (1 - \varepsilon_1) & 0 & 0 \\
\end{bmatrix},
\]
where \( P \) is the Jacobian of the transmission matrix which describes the production of new infections, whereas \( Q \) is the Jacobian of the transition matrix which describes changes in state and they are given by
\[
P = \begin{bmatrix}
\lambda \kappa_1 \kappa_2 & \pi_1 \alpha_1 \beta_1 \theta_1 & \kappa_1 \alpha_2 \beta_2 \theta_2 \\
\pi_2 \beta_1 \theta_2 & 0 & 0 \\
\kappa_2 \beta_2 \theta_2 & 0 & 0 \\
\end{bmatrix}
\]
and
\[
Q = \begin{bmatrix}
\gamma + \mu_H (1 - \varepsilon_1) & 0 & 0 \\
0 & \mu V (1 - \varepsilon_2) & 0 \\
0 & 0 & \mu U (1 - \varepsilon_3) \\
\end{bmatrix}.
\]

The basic reproduction number \( R_0 \) is the dominant eigenvalue of \( PQ^{-1} \), which can be expressed as:
\[
R_0 = \frac{1}{2} \left( R_{HH} + \sqrt{R_{HH}^2 + 4(R_{HV} + R_{HU})} \right),
\]
where
\[
R_{HH} = \frac{\pi_1 \kappa_2 \lambda}{\gamma + \mu_H (1 - \varepsilon_1)}, \quad R_{HV} = \frac{\alpha_1 \pi_1 \kappa_2 \beta_2 \theta_1}{\mu V (1 - \varepsilon_2) (\gamma + \mu_H (1 - \varepsilon_1))}, \quad R_{HU} = \frac{\kappa_1 \alpha_2 \beta_2 \theta_1}{\mu U (1 - \varepsilon_3) (\gamma + \mu_H (1 - \varepsilon_1))}.
\]

Note that \( R_{HH} \) represents the contribution to the reproduction number due to human-to-human transmission, \( R_{HV} \) represents the contribution to the reproduction number due to interaction between human and vector in a rural area, and \( R_{HU} \) represents the contribution to the reproduction number due to interaction between human and vector in the forest area. The square root arises from the two “generations” required for an infected vector or host to “reproduce” itself [20]. Moreover, the threshold of the disease occurs at \( R_0 = 1 \iff R_{HH} + R_{HV} + R_{HU} = 1 \). Also, it can be easily proven that \( R_0 < 1 \) implies \( R_{HH} + R_{HV} + R_{HU} < 1 \), which means the disease to die out, all the transmission routes represented by \( R_{HH}, R_{HV} \) and \( R_{HU} \) need to be reduced. Clearly, this will also imply that \( R_0 > 1 \) whenever \( R_{HH}, R_{HV} \) or \( R_{HU} \) is greater than one.

C. Sensitivity Analysis of the Basic Reproduction Number

A fundamental and valuable numeric value for the study of infectious disease dynamics is the basic reproduction number \( R_0 \), since it predicts whether an outbreak will be expected to continue (when \( R_0 > 1 \)) or die out (when \( R_0 < 1 \)). Sensitivity analysis of the basic reproduction number allows us to determine which model parameters have the most impact on \( R_0 \). A highly sensitive parameter leads to a high quantitative variation in \( R_0 \). Moreover, sensitivity analysis highlights the parameters that must be attacked by intervention and treatment strategies. Here, we adopt the elasticity index (normalized forward sensitivity index) [21], \( E^{R_0}_P \), which computes the relative change of \( R_0 \) with respect to any parameter \( P \) as follows:
\[
E^{R_0}_P = \frac{P}{E^{R_0}_P} \lim_{\Delta P \to 0} \frac{\Delta R_0}{\Delta P} = \frac{\partial R_0}{\partial P}.
\] (3)

Evidently, the corresponding model parameters will affect the basic reproduction number either positively or negatively. The positive sign of the sensitivity indices of the parameter denotes the increase of the basic reproduction number \( R_0 \) as that parameter changes, whereas the negative sign of the sensitivity indices of the parameter denotes the decrease of the basic reproduction number \( R_0 \) as that parameter changes. Moreover, the magnitude denotes the relative importance of the spotlight parameter.

The biting rate of mosquitoes is a significant parameter of the epidemiology of the parasite or pathogen since it is directly related to the basic reproduction rate and affects the dynamics of disease transmission in both areas. It varies depending on the local abundance of vectors, vector host preferences, and host attractiveness [22]. Mosquitoes adjust their preferences depending on the availability of a specific host species to enhance their reproductive success [22].

It is also affected by environmental factors such as temperature, humidity, and larval food sources. The terms \( (1 - \kappa_1) (1 - \kappa_2) \beta_1^2 \) and \( \kappa_1 \kappa_2 \beta_2^2 \) in \( R_0 \) suggest that...
the signs of the elasticity indices of the proportion of susceptible humans, moving from rural to forest areas $\kappa_1$ and the proportion of infected humans moving from rural to forest areas $\kappa_2$, depend on the biting rates of mosquitoes $\beta_1$ and $\beta_2$. To investigate this dependence, we use relation (3) to obtain the following relations which describe the elasticity indices of $\kappa_1$ and $\kappa_2$, respectively, in terms of both $\beta_1$ and $\beta_2$, taking all other parameters to be fixed, namely, $\kappa_1 = 0.3$, $\kappa_2 = 0.2$, $\alpha_1 = 2$, $\alpha_2 = 3$, $\varepsilon_1 = 0.67$, $\varepsilon_2 = 0.06$, $\varepsilon_3 = 0.06$, $\mu_H = 0.00004$, $\mu_V = 0.07$, $\mu_U = 0.07$, $\lambda = 0.235$, $\gamma = 0.16$, $\theta_1 = 0.33$, $\theta_2 = 0.3$:

$$E^{R_0}_{\kappa_1} = \frac{0.3}{0.4112 + \frac{1}{2}\sqrt{0.6763 + 42.1241\beta_1^2 + 6.7699\beta_1^2}}$$

$$E^{R_0}_{\kappa_2} = \frac{0.2}{0.4112 + \frac{1}{2}\sqrt{0.6763 + 42.1241\beta_2^2 + 6.7699\beta_2^2}}$$

Clearly, the above two equations show that the signs of the sensitivity indices of $\kappa_1$ and $\kappa_2$ depend on the values of $\beta_1$ and $\beta_2$. This dependence is illustrated in Figure 3 based on the range of values of $\beta_1$ and $\beta_2$ given in Table I. Figure 3 shows three different regions for the signs of the indices depending on the values of $\beta_1$ and $\beta_2$, namely, a region of negative indices, a region of positive indices, and a region of negative index for $\kappa_1$ and a positive index for $\kappa_2$. These three regions are all feasible for low values of the rural mosquito’s biting rate $\beta_1$ up to a certain limit, taken here to be around $\beta_1 = 0.75$. In this case, the region of positive indices is only feasible for higher values of the forest mosquito’s biting rate $\beta_2$, taken here to be higher than 0.8. This means that the movement of susceptible and infected humans from rural to forest areas will have the effect of increasing the basic reproduction number if the disease transmission in the forest areas is relatively higher than in the rural areas.

However, for higher values of $\beta_1$, the region of positive indices is not feasible even for high values of $\beta_2$. The only feasible positive index is for $\kappa_2$, whereas the index of $\kappa_1$ remains negative for all values of $\beta_2$ since the disease transmission in the rural area is high. Using $\beta_1 = 0.35$ and $\beta_2 = 0.9$, which correspond to the region of positive indices, we calculate the elasticity indices for all parameters. The obtained values and their interpretations are listed in Table II.

![Fig. 3: Signs of the sensitivity indices of the movement rates $\kappa_1$ and $\kappa_2$ in terms of the biting rates $\beta_1$ and $\beta_2$.](image-url)

**Table II: Sensitivity indices and their interpretation.**

</table>
other hand, the recovery rate of humans $\gamma$ has the most negative sensitivity index, as it will decrease $R_0$ by 62\% when it increases by 10\%. Clearly, there is a very small positive effect of the vertical transmission of humans and both vectors $\varepsilon_1, \varepsilon_2, \varepsilon_3$ with $\varepsilon_3$ having the highest index among them.

Using the parameter values listed in Table II, the basic reproduction number is estimated to be $R_0 = 2.093$. This value is close to the one obtained in [23], in which the authors have estimated from notification data that the basic reproduction number for ZIKV in Rio de Janeiro is $R_0 = 2.33$.

D. Local Stability of the DFE

Here we discuss the local stability of the DFE by finding the eigenvalues of the linearized system. The following theorem is devoted to the local stability of the DFE, i.e., the disease would be eliminated under certain conditions.

**Theorem 2.** If $R_0 \leq 1$, the DFE of the model (2) is locally asymptotically stable. If $R_0 > 1$, it is unstable.

**Proof:** The linearized matrix of the system (2) at the disease-free equilibrium $Z^0$ is:

$$J_{Z^0} = \begin{bmatrix}
-\mu_H & -\mu_H \gamma_1 - \lambda \gamma_1 \gamma_2 & 0 & 0 \\
0 & -\gamma - \mu_H (1 - \varepsilon_1) + \lambda \gamma_1 \gamma_2 & 0 & 0 \\
0 & \gamma & -\mu_H & 0 \\
0 & -\beta_1 \gamma_2 \theta_1 & 0 & -\mu_V \\
0 & \beta_1 \gamma_2 \theta_1 & 0 & 0 \\
0 & -\beta_2 \varepsilon_2 \theta_2 & 0 & 0 \\
0 & \beta_2 \varepsilon_2 \theta_2 & 0 & 0 \\
\gamma_1 \omega_1 \beta_1 \varepsilon_1 & 0 & -\gamma_1 \omega_2 \beta_2 \varepsilon_1 & 0 \\
\gamma_1 \omega_1 \beta_2 \varepsilon_1 & 0 & \gamma_1 \omega_2 \beta_2 \varepsilon_1 & 0 \\
0 & 0 & 0 & -\mu_V \\
-\mu_V (1 - \varepsilon_2) & 0 & -\mu_V & -\mu_U \\
0 & 0 & 0 & -\mu_U (1 - \varepsilon_3)
\end{bmatrix}$$

with

$$k_1 = \xi (1 - R_{HH}) + \mu_V (1 - \varepsilon_2) + \mu_U (1 - \varepsilon_3),$$

$$k_2 = \xi \mu_V (1 - \varepsilon_2) (1 - R_{HH} - R_{HV}) + \xi \mu_U (1 - \varepsilon_3) (1 - R_{HH} - R_{HU}) + \mu_V \mu_U (1 - \varepsilon_2) (1 - \varepsilon_3),$$

$$k_3 = \xi \mu_V \mu_U (1 - \varepsilon_2) (1 - \varepsilon_3) (1 - R_{HH} - R_{HV} - R_{HU}),$$

where $\xi = (\gamma + \mu_H (1 - \varepsilon_1))$.

It is clear that $k_3 > 0$ if $R_{HH} + R_{HV} + R_{HU} < 1$ which also implies that $k_1 > 0$ and $k_2 > 0$. Hence, in order to use Routh’s stability criterion [24] to show that the roots of the above characteristic equation have negative real parts, it remains to show that $k_1 k_2 - k_3$ is positive, that is:

$$k_1 k_2 - k_3 = 2 \xi \mu_V \mu_U (1 - \varepsilon_2) (1 - \varepsilon_3) (1 - R_{HH}) + \xi^2 \mu_V (1 - \varepsilon_2) (1 - R_{HH}) (1 - R_{HH} - R_{HV}) + \xi^2 \mu_U (1 - \varepsilon_3) (1 - R_{HH}) (1 - R_{HH} - R_{HU}) + \xi \mu_V^2 (1 - \varepsilon_2)^2 (1 - R_{HH} - R_{HV}) + \xi \mu_U^2 (1 - \varepsilon_3)^2 (1 - R_{HH} - R_{HU}) + \mu_V^2 \mu_U (1 - \varepsilon_2)^2 (1 - \varepsilon_3) + \mu_V \mu_U^2 (1 - \varepsilon_2) (1 - \varepsilon_3)^2.$$ 

Clearly, $k_1 k_2 - k_3 > 0$ if and only if $R_{HH} + R_{HV} < 1$ and $R_{HH} + R_{HU} < 1$.

Therefore, by Routh’s stability criterion, the roots of the characteristic equation $k(\ell) = 0$ have negative real parts, and hence we conclude that the DFE is locally asymptotically stable whenever $R_0 \leq 1$. Otherwise, it is unstable.

E. Global Stability of the DFE

When the solution of the dynamical system (2) approaches a unique equilibrium point regardless of initial conditions then the equilibrium point is globally asymptotically stable. The global stability of the DFE will ensure that the disease is eliminated under all initial conditions. In this regard, we state and prove the following theorem:

**Theorem 3.** If $R_0 \leq 1$, the disease-free equilibrium $Z^0$ is globally asymptotically stable on the compact set $\Omega$.

**Proof:** Applying Castillo-Chavez theorem [25], consider the following two compartments:

$$X(t) = \begin{bmatrix} S_H(t) \\ R_H(t) \\ S_V(t) \\ S_U(t) \end{bmatrix}, \quad Y(t) = \begin{bmatrix} I_H(t) \\ I_V(t) \\ I_U(t) \end{bmatrix},$$
Al-Maqrashi et al, Investigating the Role of Mobility between Rural Areas and Forests on the Spread of Zika

which describe the uninfected and infected individuals of the system (2), respectively. So that system (2) can be written as:

\[
\frac{dX}{dt} = F(X,Y), \quad \frac{dY}{dt} = G(X,Y), \quad G(X,0) = 0,
\]

where \(F(X,Y)\) and \(G(X,Y)\) are the corresponding right hand side of system (2). To guarantee the global asymptotic stability of the DFE, according to the Castillo-Chavez theorem, the following two conditions must be satisfied:

(H1) For \(\frac{dX}{dt} = F(X,0)\),

\(X^0 = (1,0,1,1)^T\) is globally asymptotically stable.

(H2) \(\hat{G} \geq 0\), where \(G(X,Y) = AY - G(X,Y)\) and 

\[A = \begin{bmatrix}
-\mu_H S_H + \mu_H & -\mu_H R_H \\
-\mu_V S_U + \mu_V & -\mu_V S_U + \mu_V \\
\end{bmatrix}.
\]

To check the first condition, we find:

\[F(X,0) = \begin{bmatrix}
-\mu_H S_H + \mu_H \\
-\mu_H R_H \\
-\mu_V S_U + \mu_V \\
\end{bmatrix}.
\]

Solving the system of ODEs in (H1), we obtain the following behavior of each component:

\[S_H(t) = 1 + S_H(0)e^{-\mu_H t} \quad \Rightarrow \quad \lim_{t \to \infty} S_H(t) = 1,
\]

\[R_H(t) = R_H(0)e^{-\mu_H t} \quad \Rightarrow \quad \lim_{t \to \infty} R_H(t) = 0,
\]

\[S_V(t) = 1 + S_V(0)e^{-\mu_V t} \quad \Rightarrow \quad \lim_{t \to \infty} S_V(t) = 1,
\]

\[S_U(t) = 1 + S_U(0)e^{-\mu_V t} \quad \Rightarrow \quad \lim_{t \to \infty} S_U(t) = 1.
\]

Hence, the first condition is satisfied. Now, to check the second condition, we find:

\[A = \begin{bmatrix}
-\xi + \lambda \xi_1 & \xi_1 \beta_1 \theta_1 & \kappa_1 \alpha_2 \beta_2 \theta_1 \\
\beta_1 \beta_2 \theta_2 & -\mu_V(1 - \varepsilon_2) & 0 \\
\kappa_2 \beta_2 \theta_2 & 0 & -\mu_U(1 - \varepsilon_3)
\end{bmatrix},
\]

where \(\xi = (\gamma + \mu_H(1 - \varepsilon_1))\). Then,

\[
\hat{G}(X,Y) = AY - G(X,Y) =
\begin{bmatrix}
(\xi_1 \beta_1 \theta_1 + \kappa_1 \alpha_2 \beta_2 \theta_1 + \kappa_1 \alpha_2 \beta_2 \theta_1)(1 - S_H) \\
\beta_1 \beta_2 \theta_2 I_H(1 - S_V) \\
\beta_2 \kappa_2 \beta_2 \theta_2 I_H(1 - S_U)
\end{bmatrix}
\]

Since \(0 \leq S_H \leq 1, 0 \leq S_V \leq 1\) and \(0 \leq S_U \leq 1\) then \(\hat{G} \geq 0\) for all \((X,Y) \in \Omega\). Thus, \(Z^0\) is globally asymptotically stable if \(R_0 \leq 1\).

F. Existence of Endemic Equilibrium

The endemic equilibrium is the state where the infection cannot be totally eradicated and the disease progression persists in a population at all times but in relatively low frequency. Here, we discuss the existence of endemic equilibrium.

**Theorem 4.** For model (2) there exists an endemic equilibrium \(Z^*\in \Omega\) whenever \(R_0 > 1\).

**Proof:** Let \(Z^* := (S^*_H, I^*_H, R^*_H, S^*_V, I^*_V, S^*_U, I^*_U)\) be the endemic equilibrium of the model (2) such that:

\[
S^*_H = \frac{\mu_H - (\gamma + \mu_H)I^*_H}{\mu_H},
\]

\[
R^*_H = \frac{\gamma I^*_H}{\mu_H},
\]

\[
S^*_V = \frac{\mu_V(1 - \varepsilon_2) - \mu_H(1 - \varepsilon_2) + \mu_H(1 - \varepsilon_2)}{\mu_V(1 - \varepsilon_2) + \mu_H(1 - \varepsilon_2) + \mu_H(1 - \varepsilon_2)},
\]

\[
I^*_V = \frac{\mu_H(1 - \varepsilon_3) + \mu_H(1 - \varepsilon_3) + \mu_H(1 - \varepsilon_3)}{\mu_H(1 - \varepsilon_3) + \mu_H(1 - \varepsilon_3) + \mu_H(1 - \varepsilon_3)},
\]

\[
S^*_U = \frac{\mu_V(1 - \varepsilon_2) - \mu_H(1 - \varepsilon_2) + \mu_H(1 - \varepsilon_2)}{\mu_V(1 - \varepsilon_2) + \mu_H(1 - \varepsilon_2) + \mu_H(1 - \varepsilon_2)},
\]

\[
I^*_U = \frac{\mu_H(1 - \varepsilon_3) + \mu_H(1 - \varepsilon_3) + \mu_H(1 - \varepsilon_3)}{\mu_H(1 - \varepsilon_3) + \mu_H(1 - \varepsilon_3) + \mu_H(1 - \varepsilon_3)},
\]

and \(I^*_H\) satisfies the following equation:

\[q_1 I^*_H^4 + q_2 I^*_H^3 + q_3 I^*_H^2 + q_4 I^*_H = 0,
\]

where

\[
q_1 = \beta_1 \beta_2 \lambda \theta_2 \kappa_2 \pi_2(\gamma + \mu_H),
\]

\[
q_2 = \xi_1 \beta_1 \beta_2 \lambda \theta_2 \kappa_2 \pi_2(1 - R_{HH}) + \xi_2 \beta_1 \beta_2 \lambda \theta_2 \kappa_2 \pi_2(1 - R_{HV})(1 - R_{HH} + R_{HV}) + \xi_3 \beta_2 \lambda \theta_2 \kappa_2 \pi_2(1 - R_{HH})(1 - R_{HH} + R_{HV}),
\]

\[
q_3 = \beta_1 \beta_1 \lambda \theta_2 \kappa_2 \pi_2(1 - R_{HH}) + \beta_1 \beta_2 \lambda \theta_2 \kappa_2 \pi_2(1 - R_{HH})(1 - R_{HH} + R_{HV}) + \xi_2 \beta_1 \beta_2 \lambda \theta_2 \kappa_2 \pi_2(1 - R_{HH})(1 - R_{HH} + R_{HV}),
\]

\[
q_4 = \xi_1 \mu_V \mu_H \mu_U (1 - \varepsilon_2)(1 - \varepsilon_3)(1 - R_{HH} - R_{HV} + R_{HH} + R_{HV},
\]

where \(\xi = (\gamma + \mu_H(1 - \varepsilon_1))\).

Solving the above equation we get \(I^*_H = 0\), which corresponds to the DFE \((Z^0)\) and the remaining roots satisfy the cubic equation:

\[q^3 + q_2 I^*_H^2 + q_3 I^*_H + q_4 = 0.
\]

Clearly, if \(R_{HH} + R_{HV} + R_{HH} > 1\), then the above equation has a positive root, since \(q_1 > 0\) and \(q_4 < 0\).
Al-Maqrashi et al, Investigating the Role of Mobility between Rural Areas and Forests on the Spread of Zika

At $R_0 = 1$, we can check that the constant term of the characteristic equation of $J_{Z^0}$ is zero which implies that $J_{Z^0}$ has a simple zero eigenvalue. Here, we choose $\lambda$ as a bifurcation parameter such that the bifurcation value corresponding to $R_0 = 1$ is given by:

$$\lambda^* = \frac{(\gamma + \mu_H(1-\varepsilon_1))(1 - R_{HV} - R_{HU})}{\kappa_1 \kappa_2}.$$  

Solving $J_{(Z^0, \lambda^*)}v = 0$, where

$$v = (v_1, v_2, v_3, v_4, v_5, v_6, v_7)^T$$

is a nonzero right eigenvector of $J_{(Z^0, \lambda^*)}$ corresponding to the zero eigenvalue, we obtain:

$$v = \begin{bmatrix}
\gamma + \mu_H \\
\mu_H \\
\gamma \\
1 \\
\beta_1 \kappa_2 \mu_H \\
\beta_1 \kappa_2 \mu_H \\
\mu_U \gamma (1 - \varepsilon_3) \\
\beta_2 \kappa_2 \mu_H \\
\mu_U \gamma (1 - \varepsilon_3)
\end{bmatrix} \begin{bmatrix} v_3 \end{bmatrix}, \quad v_3 \neq 0.$$

Next we find the corresponding nonzero left eigenvector

$$w = \begin{bmatrix} w_1, w_2, w_3, w_4, w_5, w_6, w_7 \end{bmatrix}^T$$

which satisfies $J_{(Z^0, \lambda^*)}^T w = 0$. We get:

$$w = \begin{bmatrix}
0 \\
1 \\
0 \\
0 \\
\alpha_1 \beta_1 \kappa_1 \theta_1 \\
\mu_U (1 - \varepsilon_3) \\
\alpha_2 \kappa_1 \theta_1 \\
\mu_U (1 - \varepsilon_3)
\end{bmatrix} \begin{bmatrix} w_2 \end{bmatrix}, \quad w_2 \neq 0.$$

Model (2) can be written as $dZ/dt = F(Z)$, where $F(Z)$ is the right hand side of the model. Now, we check the conditions of the Sotomayor theorem and begin with finding $F_\lambda(\lambda^*, Z^0)$:

$$F_\lambda(\lambda^*, Z^0) = (0, 0, 0, 0, 0, 0, 0)^T.$$  

So, the first condition is satisfied:

$$w^T F_\lambda(\lambda^*, Z^0) = 0.$$  

Now, note that $q_3$ can be written in terms of $q_2$ as follows:

$$q_3 = \xi \left( \mu_H \theta_2 (\beta_2 \kappa_2 \mu_V (1 - \varepsilon_2) + \beta_1 \kappa_2 \mu_U (1 - \varepsilon_3)) + \mu_V \mu_U (1 - \varepsilon_2) (1 - \varepsilon_3) (\gamma + \mu_H) (R_{HH} + R_{HV} + R_{HU}) \right) - \frac{\mu_H}{\gamma + \mu_H} (q_2 - \xi \beta_1 \beta_2 \kappa_2 \pi_2 \theta_2 \mu_H (1 - R_{HH})).$$

To prove the uniqueness of the positive roots, we apply Descartes’s Sign Rule [26]. There exists a unique positive root when $q_2 > 0$ regardless of the sign of $q_3$ and this happens if $R_{HH} < 1$ and $R_{HH} + R_{HV} + R_{HU} > 1$. However, when $q_2 < 0$ and $R_{HH} + R_{HV} + R_{HU} > 1$ there exist at least one positive root. Note that the existence of three positive roots is only possible when $q_2 < 0$ and $q_3 > 0$.

G. Bifurcation Analysis

When the stability of a system is changed as a parameter changes causing the emergence or disappearance of new stable points, then the system is said to undergo bifurcation. In this section, we prove that system (2) has transcritical bifurcation. The proof is based on the Sotomayor theorem described in [27]. Let $F$ be defined as the right-hand side of the system (2) and

$$Z = (S_H, I_H, R_H, S_V, I_V, S_U, I_U)^T.$$  

Fig. 4: Bifurcation figure when $\lambda$ is taken as a bifurcation parameter of system (2) with a bifurcation value $\lambda^* = 0.2132$ at $R_0 = 1$ and by fixing parameter $\alpha_1 = 2$, $\alpha_2 = 3$, $\kappa_1 = 0.3$, $\kappa_2 = 0.2$, $\varepsilon_1 = 0.67$, $\varepsilon_2 = 0.06$, $\varepsilon_3 = 0.06$, $\mu_H = 0.00004$, $\mu_V = 1/14$, $\mu_U = 1/14$, $\beta_1 = 0.15$, $\beta_2 = 0.1$, $\gamma = 0.16$, $\theta_1 = 0.33$, $\theta_2 = 0.3$. At $R_0 = 1$, we can check that the constant term of the characteristic equation of $J_{Z^0}$ is zero which implies that $J_{Z^0}$ has a simple zero eigenvalue. Here, we choose $\lambda$ as a bifurcation parameter such that the bifurcation value corresponding to $R_0 = 1$ is given by:

$$\lambda^* = \frac{(\gamma + \mu_H(1-\varepsilon_1))(1 - R_{HV} - R_{HU})}{\kappa_1 \kappa_2}.$$  

Solving $J_{(Z^0, \lambda^*)}v = 0$, where

$$v = (v_1, v_2, v_3, v_4, v_5, v_6, v_7)^T$$

is a nonzero right eigenvector of $J_{(Z^0, \lambda^*)}$ corresponding to the zero eigenvalue, we obtain:

$$v = \begin{bmatrix}
\gamma + \mu_H \\
\mu_H \\
\gamma \\
1 \\
\beta_1 \kappa_2 \mu_H \\
\beta_1 \kappa_2 \mu_H \\
\mu_U \gamma (1 - \varepsilon_3) \\
\beta_2 \kappa_2 \mu_H \\
\mu_U \gamma (1 - \varepsilon_3)
\end{bmatrix} \begin{bmatrix} v_3 \end{bmatrix}, \quad v_3 \neq 0.$$

Next we find the corresponding nonzero left eigenvector

$$w = \begin{bmatrix} w_1, w_2, w_3, w_4, w_5, w_6, w_7 \end{bmatrix}^T$$

which satisfies $J_{(Z^0, \lambda^*)}^T w = 0$. We get:

$$w = \begin{bmatrix}
0 \\
1 \\
0 \\
0 \\
\alpha_1 \beta_1 \kappa_1 \theta_1 \\
\mu_U (1 - \varepsilon_3) \\
0 \\
\mu_U (1 - \varepsilon_3)
\end{bmatrix} \begin{bmatrix} w_2 \end{bmatrix}, \quad w_2 \neq 0.$$

Model (2) can be written as $dZ/dt = F(Z)$, where $F(Z)$ is the right hand side of the model. Now, we check the conditions of the Sotomayor theorem and begin with finding $F_\lambda(\lambda^*, Z^0)$:

$$F_\lambda(\lambda^*, Z^0) = (0, 0, 0, 0, 0, 0, 0)^T.$$  

So, the first condition is satisfied:

$$w^T F_\lambda(\lambda^*, Z^0) = 0.$$  

Now, note that $q_3$ can be written in terms of $q_2$ as follows:

$$q_3 = \xi \left( \mu_H \theta_2 (\beta_2 \kappa_2 \mu_V (1 - \varepsilon_2) + \beta_1 \kappa_2 \mu_U (1 - \varepsilon_3)) + \mu_V \mu_U (1 - \varepsilon_2) (1 - \varepsilon_3) (\gamma + \mu_H) (R_{HH} + R_{HV} + R_{HU}) \right) - \frac{\mu_H}{\gamma + \mu_H} (q_2 - \xi \beta_1 \beta_2 \kappa_2 \pi_2 \theta_2 \mu_H (1 - R_{HH})).$$

To prove the uniqueness of the positive roots, we apply Descartes’s Sign Rule [26]. There exists a unique positive root when $q_2 > 0$ regardless of the sign of $q_3$ and this happens if $R_{HH} < 1$ and $R_{HH} + R_{HV} + R_{HU} > 1$. However, when $q_2 < 0$ and $R_{HH} + R_{HV} + R_{HU} > 1$ there exist at least one positive root. Note that the existence of three positive roots is only possible when $q_2 < 0$ and $q_3 > 0$.

G. Bifurcation Analysis

When the stability of a system is changed as a parameter changes causing the emergence or disappearance of new stable points, then the system is said to undergo bifurcation. In this section, we prove that system (2) has transcritical bifurcation. The proof is based on the Sotomayor theorem described in [27]. Let $F$ be defined as the right-hand side of the system (2) and

$$Z = (S_H, I_H, R_H, S_V, I_V, S_U, I_U)^T.$$
Next, we find the Jacobian of \( F_\lambda(\lambda^*, Z) \) as follows:

\[
DF_\lambda(\lambda^*, Z) = \begin{bmatrix}
-\bar{r}_1 \bar{r}_2 I_H & -\bar{r}_1 \bar{r}_2 S_H & 0 & 0 & 0 & 0 & 0 \\
\bar{r}_1 \bar{r}_2 I_H & \bar{r}_1 \bar{r}_2 S_H & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0
\end{bmatrix}
\]

Checking the second condition, we have:

\[
w^T DF_\lambda(\lambda^*, Z^0)v = \bar{r}_1 \bar{r}_2 w_2 v_2 \neq 0.
\]

Finally, we check the third condition by finding \( D^2 F(\lambda^*, Z^0) \), where \( D^2 \) denotes the matrix of the partial derivatives of each component of \( DF(Z) \) and we get:

\[
D^2 F(\lambda^*, Z^0)(v,v) = \begin{bmatrix}
-2\lambda \bar{r}_1 \bar{r}_2 v_1 v_2 & -2\alpha \bar{r}_1 \bar{r}_2 \theta_1 v_1 v_5 & -2\kappa \alpha \beta \theta_1 v_1 v_7 \\
2\lambda \bar{r}_1 \bar{r}_2 v_1 v_2 & 2\alpha \bar{r}_1 \bar{r}_2 \theta_1 v_1 v_5 & 2\kappa \alpha \beta \theta_1 v_1 v_7 \\
0 & -2\bar{r}_2 \beta v_4 v_2 & 2\beta \bar{r}_2 \beta v_4 v_2 \\
0 & -2\bar{r}_2 \beta v_4 v_2 & 2\beta \bar{r}_2 \beta v_4 v_2 \\
0 & -2\kappa \alpha \beta \theta_2 v_6 v_2 & -2\kappa \alpha \beta \theta_2 v_6 v_2 \\
0 & -2\kappa \alpha \beta \theta_2 v_6 v_2 & 2\kappa \alpha \beta \theta_2 v_6 v_2
\end{bmatrix}
\]

Thus,

\[
w^T(D^2 F(\lambda^*, Z^0)(v,v)) = 2v_1(\alpha \beta \theta \kappa v_1 + \alpha \beta \theta v_1 + \lambda \bar{r}_1 \bar{r}_2) + 2\beta \theta \bar{r}_2 v_4 v_1 v_5 + 2\beta \theta \kappa \alpha \beta \theta v_6 v_7.
\]

By substituting the values of \( v \)'s and \( w \)'s, we get:

\[
w^T(D^2 F(\lambda^*, Z^0)(v,v)) = -\left( \frac{2\mu}{\gamma} \left( \gamma - \mu \right) \right) + \frac{2\beta^2 \kappa_1 \kappa_2 \theta_2 (1 - \varepsilon_1)}{\gamma^2 \mu_1^2 (1 - \varepsilon_3)^2} w_2 v_2,
\]

which is nonzero since \( w_2 \) and \( v_3 \) are nonzero.

Hence, the system (2) experiences an transcritical bifurcation at \( Z^0 \) as the parameter \( \lambda \) passes through the bifurcation value \( \lambda = \lambda^* \). The bifurcation diagram is created by using the MATCONT package [28] and is illustrated in Figure 4. This leads us to establish the following theorem:

**Theorem 5.** Model (2) undergoes transcritical bifurcation at the DFE \( (Z^0) \) when the parameter \( \lambda \) passes through the bifurcation value \( \lambda = \lambda^* \).

**Remark.** We can establish the local stability of endemic equilibrium using the above calculations. We note that based on Theorem 4 in [20], \( a \) and \( b \) are given by:

\[
a = \frac{1}{2} w^T(D^2 F(\lambda^*, Z^0))(v,v) = 0
\]

\[
b = w^T(D^2 F(\lambda^*, Z^0))v = \sum_{i,j=1}^n v_i w_j \left( \frac{\partial^2 F_i}{\partial x_j \partial \lambda} \right)(\lambda^*, Z^0).
\]

According to the calculations in this section, it is clear that \( b = 0 \) and \( a < 0 \) if \( w_2 \) is positive. Thus, there exists \( \delta > 0 \) such that the endemic equilibrium \( Z^* \) is locally asymptotically stable near \( Z^0 \) for \( 0 < \lambda < \delta \). Moreover, according to Castillo-Chavez and Song [29] the direction of the bifurcation of the system (2) at \( R_0 = 1 \) is forward (supercritical bifurcation).

**IV. Numerical Analysis**

In this section, the foregoing theoretical results are confirmed by presenting the numerical results of the Zika SIR-SI model (2). The asymptotic behavior of the model is characterized by solving the system numerically using the numerical simulations of MATLAB with baseline parameters listed in Table 1 with appropriate initial conditions. We assume that the human population size is 200000, the rural mosquito population size is 400000, and the forest mosquito population size is 600000. These values are obtained by taking into consideration desired conditions or from literature.

Phase diagram for the case \( R_0 < 1 \) is illustrated in Figure 5. Here, the biting rates of rural and forest mosquitoes on humans are taken to be \( \beta_1 = \beta_2 = 0.3 \). Figure 5 shows that all populations reach the disease-free equilibrium with the disease disappearing from vector populations faster than the human population.

For the case \( R_0 > 1 \), we consider \( g_2 > 0 \) and \( g_3 > 0 \) and the biting rate of rural mosquitoes and of forest mosquitoes on humans to be \( \beta_1 = 0.35 \), \( \beta_2 = 0.8 \), respectively. The unique endemic equilibrium for this case is given by:

\[
Z^* := (0.05867, 0.00054, 0.940789, 0.99808, 0.00192, 0.99890, 0.00109)
\]

and the disease dynamics are illustrated in Figure 6. It shows that the solution exhibits oscillations before reaching its steady state.

Now, we present numerical simulations for the effects of variations of \( \kappa_1 \) and \( \kappa_2 \). In Figure 7, we change the
fraction of susceptible humans moving to forest area $\kappa_1$ and fix the other parameters as listed in Table II. We note that increasing the values of $\kappa_1$ leads to a slight increase in the maximum of both infected humans and infected vectors in forest areas. The infections reach their maximum and their endemic steady states slightly earlier as the movement of susceptible humans increases.

Figure 8 illustrates the effect of varying the proportion of infected humans moving to forest area $\kappa_2$ and fixing all other parameters. It shows that increasing the proportion of infected humans moving to forest areas has the effect of increasing the number of infected vectors in forest areas and the number of infected humans. The time it takes to reach the maximum number of infections remains the same for the vector population and it becomes slightly earlier for the human population as $\kappa_2$ increases.

Note that when $\kappa_2 = 0$ the number of infected mosquitoes in the forest area reaches zero, which means that the disease will disappear from the forest since the model assumes that infected humans are the only source of infection for the vector population in the forest. However, there have been some reports of ZIKV being found in non-human primates, raising the possibility that they could act as reservoirs [30,31]. These sources of infection will be considered in future works.

V. Conclusion

A mathematical model of ZIKV disease including human movement and three transmission routes, namely,
human-to-human transmission, vector transmission, and vertical transmission has been proposed. The model has been analyzed and studied to investigate the role of human movement from rural areas to forest areas on the spread of ZIKV. The positivity of the solution and the boundedness of the invariant region were discussed.

The basic reproduction number $R_0$ was computed and expressed in terms of reproduction numbers related to the interactions between humans $R_{HH}$, between human and vector in rural area $R_{HV}$ and between human and vector in forest area $R_{HU}$. It was found that the threshold of the disease which occurs at $R_0 = 1$ is equivalent to $R_{HH} + R_{HV} + R_{HU} = 1$ and hence all transmission routes need to be controlled to reduce the spread of the disease.

Sensitivity analysis of $R_0$ was carried out and it showed that $R_0$ is sensitive to almost all model parameters either positively or negatively, except the parameters $\kappa_1$ and $\kappa_2$, representing the proportions of susceptible and infected humans moving to forest areas, respectively, where their signs of sensitivity indices were found to depend on the biting rates when fixing all other parameters. This dependence has been calculated and illustrated graphically.

It has been found that the indices are both positive when the forest mosquito’s biting rate is high and the rural mosquito’s biting rate is small up to a certain limit. However, this positive effect on $R_0$ was found to be very small, with $\kappa_2$ having a higher effect than $\kappa_1$. The most positive influential parameters are the biting rate

Fig. 7: Number of infected populations for different values of $\kappa_1$, where other parameters are fixed $\kappa_2 = 0.2$, $\alpha_1 = 2$, $\alpha_2 = 3$, $\varepsilon_1 = 0.67$, $\varepsilon_2 = 0.06$, $\varepsilon_3 = 0.06$, $\mu_H = 0.00004$, $\mu_V = 0.07$, $\mu_U = 0.07$, $\beta_1 = 0.35$, $\beta_2 = 0.9$, $\lambda = 0.235$, $\gamma = 0.16$, $\theta_1 = 0.33$, $\theta_2 = 0.3$.

Fig. 8: Number of infected populations for different values of $\kappa_2$, where other parameters are fixed $\kappa_1 = 0.3$, $\alpha_1 = 2$, $\alpha_2 = 3$, $\varepsilon_1 = 0.67$, $\varepsilon_2 = 0.06$, $\varepsilon_3 = 0.06$, $\mu_H = 0.00004$, $\mu_V = 0.07$, $\mu_U = 0.07$, $\beta_1 = 0.35$, $\beta_2 = 0.9$, $\lambda = 0.235$, $\gamma = 0.16$, $\theta_1 = 0.33$, $\theta_2 = 0.3$. 

Al-Maqrashi et al, Investigating the Role of Mobility between Rural Areas and Forests on the Spread of Zika
of rural and forest mosquitoes on humans, while the recovery rate of humans has the most negative impact. Then, the local and global stability of the disease-free equilibrium was derived whenever $R_0$ is less than unity. Furthermore, the system was shown to possess a unique endemic equilibrium under certain conditions, and it is locally asymptotically stable when $R_0$ is greater than unity since the direction of the bifurcation was found to be forward. The bifurcation analysis was presented both analytically and graphically. Finally, numerical simulations were presented to demonstrate the obtained theoretical results. They confirmed that the human movement from rural areas to forests has a small effect on increasing the infected human and vector populations, with the movement of infected humans having a higher effect than the movement of susceptible humans.
